20 **Running title:** Salmonella detection in sand lizard

21

22

ABSTRACT

23 Salmonellosis is one of the most urgent public health problems across the world.
24 Reptiles are a known reservoir of *Salmonella* spp. and in some regions they are also
25 associated with human salmonellosis. This concerns especially popular pet reptiles, e.g.
26 turtles or bearded dragons; however, there is also a need for studies regarding wild
27 reptiles as a pathogen source. In this study, sand lizards (*Lacerta agilis*) were
28 investigated as a potential reservoir of *Salmonella* spp. in Poznań, Poland, using cloacal
29 swabs and faecal samples. Moreover, clonal analysis of the isolates was conducted
30 using ERIC-PCR fingerprinting. Thirty eight lizards were investigated, nine of which
31 (24%) proved positive for *S. enterica* subsp. *houtenae*. The prevalence level was lower
32 than previously observed in exotic species (up to above 40%). Two clones were present
33 in several lizards. Specimens with similar clones were captured at the same location and
34 time, suggesting horizontal transfer of bacterial strains between lizards. Because the
35 isolated subspecies of *Salmonella* is very rarely reported as a causative agent of human
36 salmonellosis, sand lizards seem to pose little or no threat for public health.

39 infectious disease, environmental microbiology, clonal analysis, reptile-associated

40 salmonellosis

41

42 *Salmonella* spp. is a regular component of the microbial flora of the digestive tract in
43 reptiles (Mitchell & Shane, 2001, see also Benskin et al., 2009 for birds). In mammals
44 their presence leads to salmonellosis (Buxton, 1957) and reptiles have therefore been
45 linked to salmonellosis outbreaks in humans (Warwick et al., 2001; Hassl & Benyr,
46 2003; Mermin et al., 2004; Bauwens et al., 2006; Bertrand et al., 2008). *Salmonella*
47 *enterica* subsp. *enterica* is the most pathogenic subspecies, and transmission from pet
48 reptiles to humans has previously been reported (Woodward et al., 1997; Hidalgo-Vila
49 et al., 2007; Pedersen et al., 2009; Chen et al., 2010). Prevalence of *Salmonella* spp. in
50 reptiles is often high (e.g. Geue & Löschner, 2002: 54.1%; Briones et al., 2004: 41.5%),
51 and transovarial transfer may occur from mother to clutch (Chiodini, 1982). Other
52 studies however also report that *Salmonella* spp. is absent (Geue & Löschner, 2002).

53 Due to their close contact with humans, studies which link human salmonellosis
54 with reptiles have previously large focused on pet reptiles (e.g. *Trachemys scripta*;
55 Warwick et al., 2001; Nagano et al., 2006; CDC, 2008), and our knowledge on the
56 occurrence of *Salmonella* spp. in wild European reptiles is still very incomplete (e.g.
57 *Emys orbicularis*: Hidalgo-Vila et al., 2007, *Natrix natrix*: Wuthe et al., 1979; Rostami
58 et al., 2009, *Vipera berus*: Wuthe et al., 1979). The sand lizard (*Lacerta agilis*) is the
59 most widespread reptile species in Europe (Bischoff, 1984), but our knowledge about
60 the presence of *Salmonella* spp. is restricted to a single individual investigated which
61 was tested positively for *Salmonella sofia* (currently *S. enterica* subsp. *salamae*) several
62 decades ago (Koopman & Janssen, 1973). The aim of this study was to document the
63 occurrence of *Salmonella* in a Polish population of *L. agilis*.

64 The study was carried out in May - June 2014 in two localities in Poznań,
65 Poland (near Rusalka Lake, 52°25'38.86N, 16°52'14.63E and on the edge of Morasko
66 forest, 52°28'03.03N, 16°55'50.54E) in habitats which are strongly effected by
67 anthropogenic activities. *Lacerta agilis* is a short-legged, ground-dwelling diurnal lizard
68 with about 66 - 73mm snout-vent-length (SVL, Ekner et al., 2008).

69 Lizards were captured using nets or by hand. SVL of caught lizards were
70 measured to classify them as adult (> 45 mm SVL), sub-adults (35 – 45 mm SVL), or
71 juveniles (< 35 mm, Gvozdik 2000; Dudek et al. 2015). Juveniles were lizards in their
72 first year of life, subadults were in their second year of life, and adults were at least
73 three years old. Individuals were sexed based on the presence of femoral pores and the
74 expanded gonadal area in the tail base in males. During the mating season males also
75 have green body colouration.

76 After taking cloacal swabs, all lizards were placed overnight in separate sterile
77 boxes. On the next day, the faecal samples were collected using Amies Agar Gel
78 transport swabs (Oxoid) and processed within four hours. To avoid pseudoreplication,
79 the lizards were marked using medical cautery units (following Ekner et al., 2011), and
80 each individual was used only once. After sample collecting, all individuals were
81 released at the place of their capture. Cloacal swabs and stool specimens were
82 inoculated into Rappaport-Vassiliadis Enrichment Broth (Oxoid) and incubated 48
83 hours at 42°C. If bacterial growth was observed, the culture was inoculated onto
84 Brilliant Green Agar (Oxoid) and incubated 18-24 hours at 35°C. Lactose-negative
85 isolates were identified using API 20E kits (bioMérieux) and complementary tests for
86 utilization of malonate, mucate and salicine (Popoff & Le Minor, 2005).

87 Isolates were genotyped using ERIC-PCRs, with primers complementary to
88 enterobacterial repetitive intergenic consensus sequences. Genomic DNA was isolated
89 using the Genomic Mini Kit (A&A Biotechnology). PCR reactions with primers
90 ERIC1R and ERIC 2 were conducted in a C1000 thermal cycler (Bio-Rad) following
91 Versalovic et al. (1991). Amplicons were separated on 2% agarose gels, and banding
92 patterns were analyzed using GelCompar II 3.5 software (Applied Maths) using the
93 Dice Similarity Coefficient and UPGMA clustering. Isolates sharing DNA
94 fingerprinting patterns above 95% similarity were considered clones. The experiments
95 were done in duplicate. Prevalence and confidence limits (95 % CL) for binary,
96 presence-absence, data were calculated in Microsoft Excel 2013 (Microsoft).

97 A total of 38 individuals (13 females, 20 males, and 5 juveniles) were captured.
98 Specimens taken from 10 lizards yielded bacterial growth in Rappaport-Vassiliadis
99 Enrichment Broth. Nine of these cultures grew as typical red-coloured lactose-negative
100 colonies on Brilliant Green Agar, and were identified with API 20E as *S. enterica*.
101 Complementary tests revealed that all nine isolates were malonate- and mucate-negative
102 and salicine-positive, which allowed identifying them as *S. enterica* subsp. *houtenae*.
103 Prevalence was estimated as 0.237 (95% CL = 0.102 - 372).

104 The ERIC fingerprints consisted of 8 - 18 bands ranging from 180 bp to 6300 bp
105 in size. The dendrogram showed the presence of two clusters with 100% similarity (Fig.
106 1). The first cluster comprised isolates no. J10 and J11, cultured from lizards collected
107 on 04 July 2014; the second one consisted of isolates no J33 and J36, cultured from
108 lizards collected on 10 July 2014. With less than 90% similarity, the remaining five
109 isolates were genetically unrelated.

110 Nine out of 38 *L. agilis* individuals were positive for *S. enterica* in faecal
111 samples. Such a prevalence rate is below most previously reported values (e. g. Geue &
112 Löschner, 2002 on captive individuals: 47.4% for lizards, distributed across Agamidae
113 60%, Chamaeleonidae 71.4%, Iguanidae 62.1%, Phrynosomatidae and Scinidae 33.3%,
114 Gekkonidae 16.7%, Crotophytidae, and Poychrotidae 0%; Colubridae 96.2%, Boidae
115 56.1%). All salmonellae isolates cultured from stool and cloacal swabs were identified
116 as *S. enterica* subsp. *houtenae*. Strains of this subspecies are mostly isolated from cold-
117 blooded animals and their environment (Geue & Löschner, 2002; Popoff & Le Minor,
118 2005; Bauwens et al., 2006; Bertrand et al., 2008; Pedersen et al., 2008; Hydeskov et
119 al., 2013; Gay et al., 2014), and have also been found in intestines of wild boars (Chiari
120 et al., 2013; Zottola et al., 2013) and birds (Millán et al., 2004). Overall in reptiles, *S.*
121 *enterica* subsp. *houtenae* is the third most commonly found *Salmonella* taxon after *S.*
122 *enterica* subsp. *enterica* and *S. enterica* subsp. *Diarizonae*, ahead of *S. enterica* subsp.
123 *salamae*, *S. enterica* subsp. *arizonae*, and *S. bongori* (Bertrand et al., 2008).

124 Clonal analysis showed the presence of two clusters consisting of isolates with
125 identical ERIC fingerprintings, i.e. clones. These clones were cultured from lizards
126 captured at the same day and location (Morasko and Rusalka Lake, respectively). This
127 suggests that strains of *Salmonella* spp. can be transmitted horizontally between lizards.
128 There is a need to investigate whether transovarial transfer of *Salmonella* spp. can occur
129 in sand lizards, as is the case for snakes (Chiodini, 1982).

130 The frequent occurrence of *S. enterica* subsp. *houtenae* likely poses little or no
131 threat for public health, as this subspecies is only very rarely reported in pet reptiles and
132 as a causative agent of human salmonellosis (Bertrand et al., 2008; Hoszowski et al.,

133 2000, 2012; Sadkowska-Todys & Czarkowski, 2013). There is however a need for
134 further studies on other common reptile species as potential reservoirs for *Salmonella*.
135

136 ACKNOWLEDGEMENTS

137 We thank the Editor and two anonymous Reviewers for their constructive comments.
138 This work was supported by a grant for young scientists no. 507.511.06 from the
139 Ministry of Science and Higher Education of Poland. Lizards were caught by using a
140 method that meets Polish legal standards and in accordance with the rules set by the
141 Ethics Committee for Animal Experimentation (LKE 25/2013).
